

1. **Exercise 1 (12 Points)** Let $X_i \sim \mathcal{N}(\theta, \sigma^2)$ be iid random variable where $\sigma^2 = 4$. Consider the problem $H_0 : \theta = 1$ versus $H_1 : \theta \neq 1$. Employ a (two-sided) Z-test for this, that is H_0 is rejected if $\frac{|\bar{x} - \theta_0|}{\frac{\sigma}{\sqrt{N}}} > z_{\alpha/2}$.

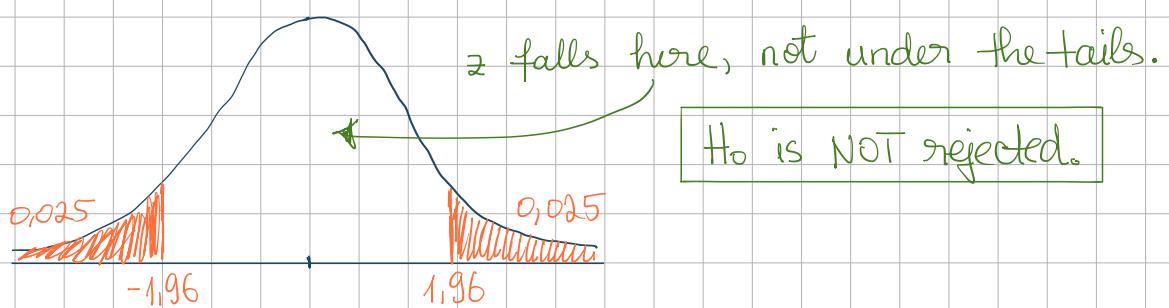

- (a) Test if H_0 is accepted or rejected for $\alpha = 0.05$ for observed $\bar{x} = 1.5$ with $n = 15$.

$$z = \frac{|\bar{x} - \theta_0|}{\frac{\sigma}{\sqrt{N}}} = \frac{|1.5 - 1|}{\frac{2}{\sqrt{15}}} = \frac{0.5 \cdot \sqrt{15}}{2} \approx 0.968$$

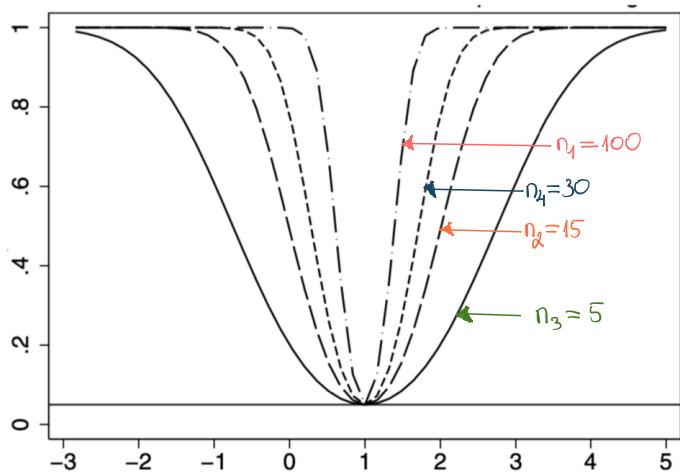

Since $\alpha = 0.05 \Rightarrow \frac{\alpha}{2} = 0.025$, we can either look up the critical value for one-sided test with $\alpha = 0.05$ or for two-sided test with 0.025. Either way:

$$z_{\alpha/2} = 1.96$$

Now we compare z and $z_{\alpha/2}$: $0.968 < 1.96$

- (b) In the figure 1, the associated power functions for different number of samples are given. Determine which power function is associated with which sample sizes: $n_1 = 100, n_2 = 15, n_3 = 5$ and $n_4 = 30$. Provide reasoning for each of your assignments.

With a small sample size, the distribution tends to have a larger standard deviation. In other words, we get a wider bell curve. For this reason, $n_3 = 5$ corresponds to the curve with the uninterrupted line.

As we increase the sample size, we become more "confident" in the value of the mean. That is, the distribution is more concentrated around the mean, with a smaller variance / std. Therefore, we assign $n_2 = 15$ to the long-dashed line and $n_4 = 30$ to the short-dashed one.

around the mean, with a smaller variance / std. Therefore, we assign $n_2 = 15$ to the long-dashed line and $n_4 = 30$ to the short-dashed one.

Finally, we assign $n_1=100$ to the wave with the highest concentration around the mean (smallest std).

- (c) Determine a confidence interval for the error probability $\alpha = 0.05$ if the empirical mean $\bar{x} = 1.5$ was calculated for a sample of size $n = 15$. That is, determine an interval $(\bar{x} - a, \bar{x} + a)$ which contains the true parameter θ with probability α .

$$\bar{x} - \underbrace{z_{\alpha} \frac{\sigma}{\sqrt{n}}}_{a} \leq \theta \leq \bar{x} + \underbrace{z_{\alpha} \frac{\sigma}{\sqrt{n}}}_{a} \rightarrow CI = (\bar{x} - a, \bar{x} + a)$$

$$\text{To find } z_{\alpha}: AL = \frac{CL + 1}{2} = \frac{.95 + 1}{2} = \frac{1.95}{2} = .975$$

$$z_{\alpha} = 1.96 \rightarrow \text{from the z-score table}$$

$$\bar{x} \pm 1.96 \cdot \frac{\sigma}{\sqrt{n}} = \bar{x} \pm 1.01 = 1.5 \pm 1.01$$

$$CI = (1.5 - 1.01, 1.5 + 1.01) = (0.48, 2.51)$$

NOTE: although the t-test is preferred for small samples, we used the z-test because we were given the population variance ($\sigma^2 = 2$).

- (d) What effect does an increase in the sample size have on the confidence interval calculated in (c), assuming that the empirical mean and the variance σ^2 remain unchanged?

As explained in part (b), increasing the sample size accounts for reduced standard error, which leads to a narrower confidence interval. In other words, the precision is increased and the range in which the true θ lies is smaller.

2. **Exercise 1 (12 Points)** As part of a large-scale study on Women and Pregnancy, the age of women at the birth of their first child is of interest. It is assumed that the average age of first-time mothers is over 25 years. To test this hypothesis, 49 mothers are randomly selected and asked about their age at the birth of their first child. The mean age was $\bar{x} = 26$ years.

- (a) Assume that the age of primiparous women is normally distributed with variance $\sigma^2 = 9$ known from experience. Check the statistical null hypothesis $H_0 : \theta \leq 25$ against the alternative $H_1 : \theta > 25$ at level $\alpha = 0.05$ using a (one-sided) Z-test. That is H_0 is rejected if $\frac{\bar{x}-\theta}{\frac{\sigma}{\sqrt{N}}} > z_\alpha$. Interpret your result.

$$n = 49 \quad \bar{x} = 26 \quad \sigma^2 = 9 \quad (\sigma = 3) \quad H_0: \theta \leq 25 \quad H_1: \theta > 25$$

$$\alpha = 0.05$$

$$z = \frac{\bar{x} - \theta}{\frac{\sigma}{\sqrt{n}}} = \frac{26 - 25}{\frac{3}{\sqrt{49}}} = \frac{1}{\frac{3}{7}} = \frac{7}{3} = 2.33$$

σ } std
} error

From the z-table, the critical value for $\alpha=0.05$ is 1.64. We now compare z with z_α : $2.33 > 1.64$.

Since our observed value of z is greater than the critical value, we reject the null hypothesis H_0 .

We can find the critical \bar{x} value from the z-score formula:

$$\bar{x}_c = \bar{x} + \frac{\sigma}{\sqrt{n}} z_c = 26 + \frac{3}{7} \cdot 1.64 = 25.70.$$

← The boundary beyond which we reject the null hypothesis in favor of the alternative.

- (b) How is the first type of error defined and what does it mean here?

A Type I error in hypothesis testing is defined as an incorrect rejection of the null hypothesis in favor of the alternative hypothesis.

In the task 2(a) above, we reject the statement "the average age of first time mothers is ≤ 25 " and conclude that it is over 25. If we did a Type I error, it would mean that the true average is ≤ 25 years, and our conclusion isn't true.

- (c) Determine the probability of making a type 2 error under the assumption that $\theta = 27$ is the true age of primiparae.

$$\begin{aligned} \mathbb{P}(\bar{x} \leq 27.50 \mid \theta = 27) &= \mathbb{P}\left(Z < \frac{27.5 - 27}{\frac{3}{\sqrt{7}}}\right) = \mathbb{P}(Z < 1.16) \\ &= 0.8770 \end{aligned}$$

- (d) Determine a 95% confidence interval for the age of the primiparae.

$$\begin{aligned} CI &= \left(\bar{x} - z_{0.025} \cdot \frac{\sigma}{\sqrt{n}}, \bar{x} + z_{0.025} \cdot \frac{\sigma}{\sqrt{n}}\right) = \left(26 - 1.96 \cdot \frac{3}{\sqrt{7}}, 26 + 1.96 \cdot \frac{3}{\sqrt{7}}\right) \\ &= (25.16, 26.84) \end{aligned}$$
